

We will now explicitly include damping in our model. Therefore, we rewrite the equation of motion, this time using the electron velocity v :

$$m_0 \frac{dv}{dt} + m_0 \gamma v = -eE$$

For the case of few electrons, it is often more intuitive to think of the damping time τ instead of the damping rate: $\tau = \frac{1}{\gamma}$

$$m_0 \frac{dv}{dt} + m_0 \cdot \frac{1}{\tau} \cdot v = -eE$$

The solution for v must have a similar form as the solution for x , with the ansatz $v = v_0 e^{-i\omega t}$, one obtains:

$$v(t) = -\frac{e\tau}{m_0} \frac{1}{1-i\omega\tau} E(t)$$

For the case of few electrons, one can also use the current and the conductivity to describe the behaviour of the electrons.

We have Ohm's law: $j = -Nev = \sigma E$

$$\Rightarrow j = \underbrace{\frac{Ne^2 \tau}{m_0} \frac{1}{1-i\omega\tau}}_{\sigma(\omega)} E(t)$$

AC conductivity
(optical conductivity).

We can define $\sigma(\omega) = \sigma_0 \cdot \frac{1}{1-i\omega\tau}$

with $\sigma_0 = \frac{Ne^2 \tau}{m_0}$

The optical conductivity and the dielectric function are related to each other by

$$\epsilon_r(\omega) = 1 + \frac{\sigma(\omega)}{\epsilon_0 \omega}$$

[slide]

Roughly speaking, ϵ_r is used for high frequencies and σ for low frequencies where the relation to the DC conductivity σ_0 becomes very obvious.

To further understand the optical properties of metals, let us look at some numbers.

The plasma frequency depends on the number density of free electrons: $\omega_p = \sqrt{\frac{Ne^2}{\epsilon_0 m_e}}$

The [slide] shows an overview of selected values for ϵ , ω_p , and σ_p . It is apparent that very large values of N lead to plasma frequencies in the ultraviolet spectral region. Above this frequency, metals become transparent. An example is Aluminium [slide].

An important mechanism of absorption in metals are interband transitions. Here, a

photon moves an electron from an occupied to an unoccupied band. Let us discuss this for our example of Al. The [slide] shows the band diagram (we have already mentioned this before. When you look closely, you can see the backfolded free electron bands).

The absorption rate is proportional to the density of states in the final state

This is Fermi's golden rule:

$$W_{\text{abs}} = \frac{2\pi}{\hbar} | \langle f | H' | i \rangle |^2 \text{ DOS in final state}$$

We thus have strong absorption for energies corresponding to a transition between an initial state with a high density and a final state with a high density.

This is the case if the bands are parallel (only direct transitions have to be considered due to the small k of the photon).

Two such transitions are marked in the diagram. They cause the dip in the reflectivity of Al at 7.5 eV. The overall slightly decreased reflectivity above 7.5 eV is caused by higher intra band transitions which are not so pronounced due to the absence of the parallel band effect.

Our second example is copper. Here, in addition to the s-bands found in Al, the d-bands are important [slide]. The 3d band has a pronounced and narrow maximum as the overlap between the d orbitals is small. Consequently, absorption will increase significantly for energies where intra band transitions from the 3d band are allowed.

This can be also seen in the full band structure. [slide]. The experimental curve for the reflectivity thus drops off significantly even well before the plasma

edge V_{slide} . The onset of the intraband transition above $2eV$ explains the red color of copper. The same argument explains the yellow color of gold V_{slide} . Example: slide

Now we consider the behavior of the free electrons right at the plasma frequency. Remember, that a plasma consists of a gas of charged particles in dynamic equilibrium. The particles are in constant motion, and this can create local charge fluctuations. When say such a fluctuation a small region with an excess charge is created, a force is acting on these electrons with the goal of reaching a homogeneous distribution again. The velocity acquired by the electrons can lead to overshooting and in consequence to an oscillatory motion, the plasma oscillation which have their characteristic frequency right at the plasma frequency.

The corresponding quasi-particle is called plasmon slide. As the plasmon is a longitudinal wave, it cannot couple with photons, which are described by a transversal wave. In the next lecture we will see that they can be detected by inelastic scattering of photons instead. This situation changes for a special plasmon mode localized at the surface

of a metal, the surface plasmon, [slide].

The associated wave propagates along the interface. The amplitude of the electric field decays exponentially on either side of the interface. It is obvious that the surface plasmon contains also transverse components of the electric field that allow coupling to photons. In the case of strong coupling it is appropriate to speak of a polariton which is a coupled electric polarization - photon wave. The most clear manifestation of surface plasmon effects is found in the optical properties of metal nanoparticles. The color of a suspension of such clusters is dominated by the plasmon resonance. This is exploited since antiquity to produce colored windows by embedding metal nanoparticles.

Quasi particle scattering

In the last chapter we have encountered the plasmon as a quasi particle describing a collective excitation of the free electron gas.

In this chapter we will see, how the plasmon and other quasiparticles can be detected via scattering with photons, electrons, or neutrons. But let us start with a brief review on the most important quasiparticle, the phonon.

Excitations of vibrations in the lattice can be described by phonons. The complex patterns of vibrations can then be treated as a superposition of these elementary excitations (slide)

The dependency of wave vector and frequency is given by the phonon dispersion relation.

The standard model system to describe Phonons is the linear diatomic chain. (slide). Note that a meaningful wave vector can only be defined inside the first Brillouin zone as otherwise the wavelength does get shorter than the unit cell, which is not meaningful as the crystal lattice is discrete. The energy states follow from the dispersion relation according to: $E_n(\mathbf{k}) = \hbar\omega(\mathbf{k}) \left(n + \frac{1}{2}\right)$

As an example, the phonon dispersion of the fcc lattice is shown (slide) for the case of Si.

There are two classifications used to describe phonons: longitudinal/transversal and acoustical/optical. For longitudinal phonons, the displacement of the atoms occurs parallel to the direction of the wave, whereas for transversal phonons this displacement is perpendicular to the wave vector. For acoustic phonons, the atoms inside the unit cell move all in the same direction, whereas for optical phonons, these atoms vibrate against each other. When the charges in a crystal are not evenly distributed (e.g. in an ionic crystal), an optical phonon induces an oscillating dipole moment, which allows coupling of these optical phonons to photons. As light is a transversal wave, only coupling to transversal phonons is possible.

We have encountered these phonons already in the last chapter as the vibrational oscillators in the Lorentz-model.

A possible way to describe this interaction is in the quasiparticle picture. Here, momentum and energy have to be conserved during absorption of a photon by a phonon. The comparison of the dispersion relation of phonons and photons [slide] shows, that this is only possible for the optical branch of the phonon dispersion curve.

We will now turn to the basics of inelastic scattering, which is a means to detect quasi-particles. To start general, we do not yet specify whether the scattered particle is a photon, electron, or neutron. Let us look at the conservation laws for scattering [slide].

First, we have conservation of momentum. Here, we have to remember that due to the broken translational symmetry of space induced by the crystal, momentum is only conserved up to additions of reciprocal lattice vectors.

$$\text{We have: } \vec{Q} = \vec{q} + \vec{G} = \vec{k}' - \vec{k} \quad \begin{matrix} \text{incident} \\ \text{and} \\ \text{scattered} \\ \text{wave} \end{matrix}$$

↓
 momentum transfer
 ↓
 momentum of phonon

↓
 reciprocal lattice vector

In addition, we have conservation of energy:

$$E = E' + E_{\text{Phonon}},$$

which can be used to calculate E_{Phonon} .

For the case of electrons or neutrons, we have $E = \frac{\hbar^2 k^2}{2m}$ and hence

$$E_{\text{Phonon}} = \hbar \omega_{\text{ph}} = \frac{\hbar^2}{2m} (k'^2 - k^2).$$

For photons, we have:

$$E_{\text{Phonon}} = \hbar \omega_{\text{ph}} = \hbar (\omega - \omega').$$

Furthermore, spin is conserved.

Let us now look at scattering of photons, which is known as Raman scattering around [slide] the visible part of the spectrum. These photons have a very small wave vector:

$$k_0 = \frac{2\pi}{\lambda} \approx \frac{2\pi}{4000 \text{ Å}} \approx 1 \cdot 10^{-3} \text{ Å}^{-1}$$

The edge of the Brillouin zone ($\hat{\equiv}$ maximum wave vector of the phonon) is found at

$$\frac{\pi}{a} = \frac{\pi}{2 \text{ Å}} \approx 1.5 \text{ Å}^{-1} \quad \text{Therefore, visible}$$

light is only sensitive to phonons at the very center of the Brillouin zone. Raman Spectroscopy can also detect other quasi particles, as the plasmon encountered in the previous chapter.

The schematic setup is shown in the [slide]. As a monochromatic source of high intensity is needed (Raman scattering has a low probability as compared to elastic - Rayleigh-scattering) the laser is the right choice.

The very large elastic signal is then filtered and the remaining light is analyzed in a spectrometer.

The atomic processes in Raman scattering can also be visualized in an energy level scheme (slide) using virtual energy levels. Besides the creation of a phonon (Stokes process), an existing photon can also be absorbed by the photon (Anti-Stokes).

Anti-Stokes scattering will only be possible if there are phonons present in the material before the light is incident. The probability for anti-Stokes scattering therefore decreases on lowering the temperature as the phonon population decreases. On the other hand, Stokes scattering does not require a phonon to be present and can therefore occur at any temperature. As the population of a given phonon level follows a Boltzmann distribution, the ratio of anti-Stokes to Stokes scattering events is given by:

$$\frac{I_{\text{anti-Stokes}}}{I_{\text{Stokes}}} = e^{-\hbar \omega_p / k_B T} \quad [\text{slide}]$$

Inelastic light scattering is a weak process. This is because we are dealing with a higher-order interaction than for linear interactions such as absorption. As an example the [slide] shows a Raman spectrum of GaAs, where the TO and LO phonon are visible. In addition, a weaker peak due to the plasmon occurs.

Recall,

Raman spectroscopy was extensively applied to the new material graphene, as it allows (i) to distinguish single-, bi-, and few layer graphene and (ii) allows to assess the quality (defect density) [slide].

A Raman microscope can be used to spatially resolve the vibrational properties of the sample, see the [slide] for a example.

For excitations very close to the M-point, the dispersion of these modes can be detected by Raman spectroscopy. This reveals coupling between different modes: The [slide] shows how the photon and the TO phonon form a polariton in GaP, leading to avoided crossing (anticrossing). Generally, a polariton is a coupling between a photon and a phonon/plasmon/exciton.

The spatial resolution can be enhanced even further by performing Raman Spectroscopy inside an STM or AFM: Tip-enhanced Raman Spectroscopy (TERS). The basic effect is

that the local electric field can be enhanced in a gap between the surface and a metallic tip of the right shape and material (slide).

The main Raman signal thus comes from the small area underneath the tip and can be related to the topography measured simultaneously. Hence, vibrations of single molecules can be detected, e.g. RNA [slide]

In optical measurements only phonons at the center of the Brillouin zone ($\vec{q} \approx 0$) can be studied, since energy and momentum conservation can be satisfied only here on account of the great disparity between phonon and photon propagation velocities. The situation is different for neutrons. The [slide] used to illustrate this was already shown in the context of diffraction. It shows the dispersion relation for photons, neutrons and electrons (and He).

The region where the phonons live is the intersection of the blue bars (wavelength on the order of interatomic distances, energy in the range of thermal excitations). Of course, $\lambda = \frac{2\pi}{k}$. Only neutrons have the right energy and momentum to map the whole Brillouin zone easily. Therefore, they are the ideal probe to detect phonons.

The experimental setup used here is the triple-axis - spectrometer [slide]. A white beam of neutrons is produced in a reactor and monochromatized using Bragg reflection. The wavelength of the incoming light is selected by turning the monochromator around the first axis. The orientation of the sample with respect to the beam is altered using the second axis. After the scattering event, the (now reduced) energy of the neutrons is measured

using again Bragg reflection around the $\bar{L}\bar{Y}$ axis. Variation of incident energy, final energy, scattering angle and sample orientation allows to map the whole Brillouin zone. The [slide] shows an example.

Due to their sensitivity to the magnetic moment, inelastic neutrons are also the right probe for the detection of spin waves or magnons (slide). These are collective excitations of the electrons' spin structure in a lattice. The [slide] shows an example of a measured magnon dispersion curve.

The last method we will discuss is inelastic scattering of electrons, called electron energy loss spectroscopy. Often, an instrument we already mentioned, namely the TEM, is used to detect these signals. Although electrons with the right wavelength (or momentum) have rather high energies as compared with photons, electrons can be detected with a very good energy resolution making EELS a feasible method. The setup of a TEM with EELS is shown in the [slide]. The example [slide] shows that one can obtain the same information from EELS as from optical methods.

The ultimate energy resolution is reached in HREELS (high-resolution electron energy loss spectroscopy). Here, losses of a small fraction of a eV can be detected, because the technique allows to resolve small separations between the elastic peak and the loss features. The setup (slide) consists of a cathode system, a first energy dispersive element (a monochromator), a lens system between the monochromator and the sample, a second lens system between the sample and the analyzer, a further dispersive element (an analyzer) and finally the electron detection. One or

two sequential 127° angle cylindrical sector deflectors fixed at constant pass energy are used as a monochromator. From the broad Maxwell distribution of hot electrons emitted by the cathode, it selects electrons in a narrow energy window (typically 1-10 meV and down to a fraction of a meV in the most advanced systems). The analyzer works in a similar way. A channeltron multiplier is a conventional electron detector. The instrument is very surface sensitive. The example (slide) shows the determination of the full phonon dispersion for graphite.

Magnetism

In this chapter we will deal with experimental techniques used to measure the magnetic properties of matter. Let us start with a review of the basic properties of magnetically ordered states. The magnetic interactions between the individual moments can produce different types of magnetic ground states, some of which are illustrated on the [slide]. These include ferromagnets in which all the magnetic moments are in parallel alignment, antiferromagnets in which adjacent magnetic moments lie in anti-parallel alignment, spiral and helical structures in which the direction of the magnetic moment precesses around a cone or a circle as one moves from one site to the next, and spin glasses in which the magnetic moments lie in frozen random arrangements.

Ferromagnetism

A ferromagnet has a spontaneous magnetization even in the absence of an applied field. All the magnetic moments lie along a single unique direction. This effect is generally due to exchange interactions (direct exchange, superexchange, RKKY). For a ferromagnet in an applied magnetic field \vec{B} , the appropriate Hamiltonian to solve is:

$$H = - \sum_{ij} J_{ij} \vec{s}_i \cdot \vec{s}_j + g \mu_B \sum_j \vec{s}_j \vec{B}$$

coupling spins at
 const. positions
 i j

\nearrow \nwarrow
 g-Factor (c.c.)
 Bohr magneton

The exchange constants J_{ij} for nearest neighbours have to be positive to ensure ferromagnetic alignment. The first term on the right is the Heisenberg exchange energy, the second term is the Zeeman energy.

The ferromagnetic order evolves spontaneously:

The degree of ordering depends on Temperature and disappears above the Curie - Temperature.

The typical magnetization vs Temperature curves resulting from the mean-field model (Wuiss model) are shown in the [slide].

Note that the disappearance of M above T_c is a second order phase transition,

Anti-ferromagnetism

If the exchange interaction is negative ($J < 0$), the molecular field is oriented such that it is favorable for nearest neighbour magnetic moments to lie antiparallel to each other. This is anti-ferromagnetism. Anti-ferromagnetic order disappears above the Néel - Temperature.

Susceptibility

The magnetic susceptibility is defined

$\vec{M} = \chi \vec{H}$. From the Weiss model of magnetism it follows that:

$$\text{Ferromagnet: } \chi \sim \frac{1}{T - T_c} \quad (\text{Curie-Weiss law})$$

$$\text{Antiferromagnet: } \chi \sim \frac{1}{T + T_N} \quad (T > T_c)$$

This can be generalized by defining the Weiss temperature Θ leading to

$$\chi \sim \frac{1}{T - \Theta}$$

For a paramagnet, $\Theta = 0$, for a ferromagnet $\Theta = T_c$, and for an antiferromagnet $\Theta = -T_N$.

See the [slide] for a graphical representation.

Measuring the dependence of χ on T is therefore an experimental pathway to determine

the kind of magnetic ordering and its parameters. For an antiferromagnet, the behaviour of χ also depends on the geometry of the experiment. [slide]

For a ferromagnet, the formation of magnetic domains leads to the occurrence of hysteresis loops in the $M(H)$ curves (slide).

Experiments

The most obvious experimental technique to try is a conventional measurement of magnetization, i.e. determine the sample's net magnetic moment.

This is done using a magnetometer. This is of course only meaningful with samples having a non-zero magnetization. To have a high signal, special constructions are in use.

The first to be discussed here is the vibrating sample magnetometer (VSM). The sample is put into a uniform magnetic field in order to magnetize it. The sample is then vibrating sinusoidally, typically by using a piezo-motor.

The changing magnetic field nearby the sample induces a voltage in the pick-up coils:

$U_{\text{ind}} = -N \frac{d\Phi}{dt} \approx N M V \dot{x}$. Typically, the induced signal is detected using a lock-in amplifier taking the mechanical oscillation as a reference signal. By measuring M as a function of an external field B or as a function of T , hysteresis curves and magnetization curves can be recorded.

The most sensitive magnetometers are using also SQUIDs (superconducting quantum interference devices) as sensors. These are formed by a ring of superconducting material (silicon). As the flux through such a ring is quantized in units of $\frac{\hbar}{2e}$.

When the external magnetic field is such that in principle a non-integer number of flux quanta has to pass through the loop, a supercurrent is induced which exactly compensates the extra flux. This super current can be read out as a voltage in a ring containing two Josephson junctions. For a typical size of a SQUID, changes in the magnetic field of down to 10^{-8} T can be detected, making the SQUID one of the most sensitive detectors available. In practice, many applications exist where the quantity of interest is first turned in a magnetic signal and then measured using a SQUID.

Example: EuO [slide]

Magneto optics

In order to understand how magnetism can change the interaction of light with media, we have to take a look at the behavior of circular polarized light. For chiral objects the response towards left- and right-circular light will be different. (A chiral object is an object that can not be superimposed with its mirror image like the right and the left hand). A difference in the real part of the complex refractive index gives rise to optical activity while a difference in the imaginary part cause circular dichroism. Optical activity means that the speed of propagation is different for left- and right-circular light and has as a consequence, that the plane of polarization of linear polarized light is turned when light shines through a material with optical activity. Circular dichroism is observed in absorbing chiral materials. "Dichroic" means two-colored and is used for any optical phenomenon that affects two colors differently. In the case of circular dichroism, the absorption coefficient is sensitive to the direction of the circular polarization, which implies that if the absorption bands lie in the visible spectral region, the color will be different when viewed with left- or right-circular light.

Optical chirality can be induced by a chiral crystal structure or in non-chiral material by applying a magnetic field. This induces a number of magneto-optical phenomena. In the case of transparent materials, the field induces optical activity and the phenomenon is called either the Faraday-effect or the magneto-optical Kerr effect, depending on whether the rotation of the polarization is observed in transmission or reflection, respectively. [slide]

If the medium is absorbing, the field can induce circular dichroism, in which case we have magnetic circular dichroism.

Let us first look at the detection of the magneto-optical Kerr effect (MOKE). As a light-source, typically a laser is used. The light is polarized and focused on the sample. After reflection, the (now changed) polarization is measured. As the amount of the Kerr-rotation depends on the magnetization of the sample, this technique can be used for the measurement of hysteresis loops [slide].

This technique can also be used to obtain images by forming an image of the sample in polarisation contrast (MOKE microscope) [slide]

By this technique, the distribution of magnetic domains can be imaged [slide].

As an example for magnetic circular dichroism, we will take a look at XMCD (x-ray magnetic circular dichroism). This technique is closely related to x-ray absorption spectroscopy discussed earlier. It has the advantages that it can distinguish the magnetic contributions from different elements and that it is very sensitive. XMCD is the difference for a magnetic material between the absorption of left and right circular polarized x-rays. [Slide] In x-ray absorption, the atom absorbs a photon, giving rise to the transition of a core electron to an empty state above the Fermi level. The absorption edges have energies which are characteristic for each element. Due to the dipole selection rules for the absorption of a photon, the intensities of the absorption lines differ for the two polarizations in the presence of a magnetic field. Using the appropriate sum rules the magnetic moment per atom can be determined and one can even distinguish between orbital and spin momentum. (Slide) As this technique needs a tunable x-ray, it can only be carried out at a synchrotron.

Techniques based on the detection of electrons (LEEM, photoemission) can be turned into methods sensitive to magnetism by measuring the spin of the detected electrons. A device used to detect the spin is the Mott-detector (Mott-Polarimeter). This device is based on the spin dependence of the scattering cross section for electrons with atoms.

As the scatter, an atom with a high nuclear charge is used (e.g. gold). The scattering electron penetrates deep into the Coulomb field of the atom. In the rest frame of the electron, the atom moves towards the electron (slide). When the electron is inside the atom, the atomic charge is dominated by the positive nuclear charge. In the rest frame of the electron, the moving electric field generates a magnetic field with circular field lines. The magnetic field is inhomogeneous, it becomes weaker as the distance to the atomic nucleus increases. The large magnetic field gradient exerts a sizeable force on the magnetic moment of the electron. This force is superimposed onto the Coulomb force acting on the charge of the electron. If the magnetic moment is up and if the electron passes on the right side of the atom, magnetic field and magnetic moment are parallel and the force pushes the electron towards

increasing field, i.e. to the left. If the electron passes on the left side of the atom, magnetic field and magnetic moment are anti parallel and the force pushes the electron towards the weaker field, i.e. to the left as well. Altogether, an electron with magnetic moment up out of the scattering plane is preferentially scattered to the left, and an electron with magnetic moment down is preferentially scattered to the right. By detecting the intensities of the electron beam on both sides after the scattering, the spin direction can be determined [slide].

The next [slide] shows a setup for spin resolved ARPES. First, the photoelectrons are sorted according to energy and angle as we have learned before. In an additional step, the 3D orientation of the spin is detected using two more polarimeters. The [slide] shows as an example the spin resolved Fermi surface of Ni.

Magnetic resonance Techniques

The next techniques we will discuss are able to determine the response of an individual magnetic moment to the local environment it is sitting in. This environment is determined by the crystal field, spin-orbit coupling, and hyperfine interactions (see below). The experimental technique is based on resonant transitions between Zeeman-split states.

Nuclear magnetic resonance (NMR)

For an NMR experiment, one needs a nucleus with a non-zero spin (^1H , ^2H , ^{13}C). In a simple NMR experiment [slide], a sample is placed inside a coil which is mounted between the pole pieces of a magnet. The magnet produces a magnetic field \vec{B}_0 along the z-direction.

The z-component m_I of the angular momentum of the nucleus I can only take integral values between $-I$ and I . The energy E of the nucleus with magnetic moment $\vec{\mu}$ in the field \vec{B}_0 is then:

$$E = -\vec{\mu} \cdot \vec{B}_0 \quad \text{nuclear magneton}$$

$$= -g_N \mu_N m_I B_0$$

g-factor
of nucleus

This corresponds to a ladder of $2I+1$ equally spaced energy levels with a

mutual separation of group B_0 as illustrated in the sketch for the case $I=3/2$. For usual fields in the range of 1 T the energy separation corresponds to photons in the radio frequency regime. Therefore, transitions between adjacent pairs of levels can be excited by a radio frequency (RF) field, which is the basis of NMR. In the sketch of the NMR setup, this RF field is provided by the coil around the sample.

Only transitions where the dipole selection rule $\Delta m_I = \pm 1$ is obeyed are possible,

which implies that only transitions between adjacent states may occur.

In the most common experimental setup, the RF coil is part of a tuned circuit with a large Q factor. The (quasi-) static field B_0 is ramped up, and when the energy separation matches the frequency of the loop, energy is lost which yields the measurable signal (at the position of nuclear magnetic resonance). The resonance frequency is given by e:

$$\nu = \frac{\omega}{2\pi} = \frac{\Delta E}{2\pi k} = \frac{g \nu \mu_N}{2\pi \hbar} B_0$$

The NMR frequency can be slightly shifted depending on the chemical environment of the nucleus (chemical shift), as the

electrons orbiting the nucleus slightly shield it from the applied field. (This chemical sensitivity is the reason for the application of NMR in medical imaging). It can be also changed by nuclear spin-spin coupling mediated by the electrons, those containing information about the magnetic environment of the nucleus.

Electron spin resonance

One can perform the analogous experiment to NMR with electrons (electron spin resonance - ESR). As the magnetic moment of the electron is higher than the one of the nucleus, the resonance for typical magnetic fields is in the microwave regime! The technique is therefore based on waveguides and cavities [slide]. Again, the behaviour of the microwave circuit changes significantly when it is operated at a resonance frequency of the sample. ESR allows to detect the local crystal field. This will be explained using an atom in an octahedral environment, a situation found for the metal ion in a pyrochlore, which is the crystal structure of many transition metal oxides [slide]. The crystal field in this case arises mainly from electrostatic repulsion from the negatively charged electrons in the oxygen orbitals. The outermost

orbitals of the metal are the d-orbitals.
[slide] Close inspection reveals that the d-orbitals fall in two groups : The t_{2g} -orbitals which point between the axes (d_{xy} , d_{xz} , d_{yz}) and the e_g -orbitals which point along these axes (d_{z^2} , $d_{x^2-y^2}$). As the overlap of the e_g -orbitals with the oxygens is stronger, they will be shifted up in energy [slide]. This is the crystal-field-splitting.

The consequence of crystal-field-splitting for the ESR signal is shown on the [slide] : It leads to a splitting of the absorption lines. This can be used to evaluate the strength of the crystal field and the occupation of the d-orbitals.

Thermodynamic Properties

In this section we will see how the quantitative determination of Thermodynamic properties, can give us important information on phase transitions, and especially on magnetic ordering phenomena. The underlying formula is the dependence of the free energy F of a system on the variables T , B , and V :

$$dF = -SdT - m dB - p dV$$

(this is derived from the first law of Thermodynamics)

The relation between these quantities is shown on the circle. As the system always seeks the minimum of F , it can react to changes in one variable by spontaneous changes in the other. In the following we will focus on thermal expansion (changing the temperature changes the volume), magnetostriiction (changing the magnetic field changes the volume), and heat capacity (changing the temperature changes the entropy). We will start with looking at experimental methods to determine changes in length of samples.

Dilatometry

A dilatometer is a scientific instrument that measures volume changes induced by physical or chemical processes. Historically, the thermal expansion of solids has been studied from the beginning

of material science, see slide for an old dilatometer. In the following, we will see that the precise determination of this effect allows to learn much more than just "rails become longer in summer". In principle, several methods we have studied so far allow for a determination of thermal expansion, for example a determination of the structural parameters by x-ray or neutron diffraction. However, much more powerful methods are available slide. We will now focus on the capacitive dilatometer slide. The principle of operation is that the expansion of the sample moves one plate of a plate capacitor. Assuming circular plates with radius r , the capacitance is given by:

$$C = \epsilon_0 \frac{\pi r^2}{d}$$

The change in length is then related to the change in capacitance as:

$$\Delta L = \epsilon_0 \pi r^2 \left(\frac{1}{C_1} - \frac{1}{C_2} \right)$$

One can reach a resolution in the range of 10^{-10} m. An example for such an instrument is shown on the slide. A typical sample environment for this kind of measurements are low temperatures (a few K) and high magnetic fields (several T).

Calorimetry

Specific heat is measured with a calorimeter, see slide for a historic example. In such an ice calorimeter, the heat transferred from a body

at given starting temperature T_1 to a bath at temperature T_0 is measured by the amount of ice that can be melted with it. The same principle is used today. The basic ingredients are a temperature bath at given (low) T_0 , a heater to transfer energy to the sample, and a precise determination of sample temperature. The actual measurement can be carried out in different ways, as we will see in the following.

Nernst method (heat pulse method)

This is probably the most intuitive technique: A sample is thermally isolated from the environment as good as possible (adiabatic conditions). A defined amount of heat ΔQ is introduced by the heater and the resulting increase in sample temperature is measured (slide). In a sense, this is a direct realization of the definition of c : $c(T) = \lim_{\Delta T \rightarrow 0} \frac{Q}{\Delta T}$.

In practice, conditions close to adiabatic are difficult to realize.

Continuous heating method

This procedure is closely related to the Nernst method. Here, the sample is heated continuously under adiabatic conditions, and the heat capacitance is determined as the derivative of the resulting $T(Q)$ curve (slide). This method is less accurate than the Nernst method, but allows a fast determination with a high density of data points.

In the following two methods, the sample is in (weak) thermal contact to the bath. The principle of measurement is based on the fact, that the specific heat determines, how fast the temperature of the sample can react to external heating.

Relaxation time method

Here, the sample is heated, until a new equilibrium temperature following the competition between heating and cooling (via the external bath) has been established. Analyzing both this rise in T as well as the drop back to T_0 allows a determination of c . *(slide)*

AC method

In this approach, the sample is heated using a periodically varying heating power $P(\omega) = I_H \cdot U_H$. The sample reacts with a periodically varying temperature with amplitude ΔT . It can be shown that $C(\Delta T) = \frac{I_H \cdot U_H}{\omega \cdot \Delta T}$

Example

To get started with an example, we look at the internal energy of a ferromagnet with $S = \frac{1}{2}$ and $T_c = 10 \text{ K}$. Using mean field theory, it can be shown that the magnetic contribution to the internal energy is:

$$U^{\text{mag}} = -N \int B_{\text{eff}} dM$$

$$= -N \left(\frac{3k_B T_c S}{2(S+1)} \frac{M^2}{M_{\text{sat}}^2} + MB \right)$$

The behavior of $M(T)$ in this example is shown on the slide. In the absence of an external magnetic field B , U^{mag} is zero above T_c and becomes more and more negative the lower we go in temperature.

Right at T_c , $\frac{dU^{\text{mag}}}{dT}$ has a dis-

continuity. This discontinuity should show up both in $C = \frac{\partial Q}{\partial T}$ as well as in $\beta = \frac{1}{V_0} \frac{\partial V}{\partial T}$. Experimental results for the model compound EuC_2 ($s = \frac{1}{2}$, $T_c = 14\text{K}$) are shown on the slide. A difficulty in the evaluation is to remove other contributions to β and C (phonons).

Creation of low temperatures

Many properties of solids (e.g. magnetic ordering phenomena) can only be studied at very low temperatures slide. In the following, we will learn how these conditions can be created in the lab.

The temperatures that can technically be reached today (10^6 K) are several orders below the lowest temperatures occurring in our universe (2.73 K background radiation). One can say that the creation of ultra-low temperatures is one of the few parameters where mankind has surpassed nature.

The history of this technical development is shown on the slide. The methods dominating the refrigeration technique today are shown in the slide. Properties of matter that can only be studied at very low temperatures include the quantization of lattice vibrations (phonons), the electronic excitations leading to the linear temperature dependence of the specific heat of conduction electrons, superconductivity, superfluidity, and many aspects of magnetism.

Cryo liquids

Bringing the sample into contact with a reservoir containing a cryo liquid (LN_2 - 77K / ${}^4\text{He}$ - 4K) is the easiest method of refrigeration. Although today the supply of cryogenic liquids is a routine process, it is instructive too look briefly into the effects underlying gas liquefaction.

A general principle is for cooling is causing a gas to perform adiabatic external work. During this, it must cool due to the first law of thermodynamics. What happens is that some of the internal energy of the gas (the kinetic energy of the molecules) is used to perform the work. There are several ways how to achieve this. Technically, we will only look at an idealized version of the process, namely a Stirling engine operated in reverse cycle. Two piston and cylinders are used, one at the high temperature T_H , the other at the low temperature T_L . They are connected via a regenerator, a device which has low thermal conductivity, a small internal volume, and a low flow impedance for gas, but a large heat capacity and a large internal surface area (e.g. a tube filled with fine Cu-wire). We assume that the top of the regenerator is at T_H , whereas its bottom is at T_L . In step (a) [A \rightarrow B] the upper piston moves and compresses the gas at the hot end, while the lower piston stands still. Work is done on the gas and the heat Q_H has to be removed in order to keep T_H constant. In (b) [B \rightarrow C] both pistons move together to transfer gas from the hot to the cold side. Because of the large heat capacity of the regenerator, the gas is already at T_L when it enters the lower chamber. In (c) [C \rightarrow D] the lower piston lets the gas expand.

Work is being done by the gas, which has to be supplied by the environment as heat Q_c . This is the cooling step. In the last step (d) [$D \rightarrow A$] the system is brought back to the starting conditions, picking up the heat from the regenerator that has been stored there before. Remember that the total amount of work is the area enclosed by the path in the pV -diagram. In our process, the work is taken from the thermal energy of the cold side.

A technique of high technical importance is Joule-Kelvin expansion. Here, gas is allowed to expand through a porous plug (slide). It can be shown that during such a process the enthalpy stays constant, we therefore have to look at the isenthalps (lines of constant enthalpy) in the figure. We see that in a specific regime of the plot, the reduction in pressure due to the orifice is accompanied by a reduction in temperature. This can only happen if the gas (a real gas) was in a state where the intermolecular interaction is attractive before the plug. The expansion then increases the potential energy, and the kinetic energy (and hence the temperature) go down. As a consequence, this process is only possible in a specific regime in the pT -diagram. However, for most gases this regime is easy to reach.

In practice, one can use the cooled gas streaming out to pre cool the gas streaming in (slide). Thereby, after some time, liquefaction can be reached.

Technologically important processes (Linde process) combine several techniques. It is interesting to note that the liquefaction of air is the common procedure to separate air into its constituents.

^3He - ^4He Dillation Refrigerator

In order to go below the temperature limit that can be employed by the use of cryogens (0.03 K using liquid ^3He), the device most commonly used today is the ^3He - ^4He dillation refrigerator.

This device is based on a process suggested in 1962 by London, Clarke, and Mendoza. In contrast to using the latent heat of evaporation for cooling, here the heat of mixing of the two He isotopes is used to reach low temperatures. In order to understand this device, we have to take a look at the properties of liquid ^3He - ^4He mixtures.

The (slide) depicts the x-T phase diagram of such a mixture at saturated vapor pressure. (x is the relative concentration of ^4He). The superfluidity (fluid with zero viscosity) of ^4He due to its bosonic nature is depressed by dilating it with the fermionic ^3He . The shaded region under the phase-separation line is a non-accessible range of temperatures and concentrations.

for helium mixtures. If we cool an appropriate mixture to below 0.87 K, the liquid will phase separate, in a ^4He -rich and a ^3He -rich phase. Upon reaching 0K, we have on the one side pure ^3He , but on the other side a mixture containing 6.6% ^3He in ^4He . This finite solubility at 0K is an exceptional behaviour and of utmost importance in ^3He - ^4He dilute refrigeration technology. As we will see below, cooling in a ^3He - ^4He dilution refrigerator is achieved by transferring ^3He atoms from the pure ^3He phase to the diluted, mostly ^4He containing phase. The cooling capacity in this case is the heat of mixing. In general, if the intermolecular forces between A and B are larger than the ones in A-A and B-B, the potential energy upon mixing rises. This is compensated by a loss in kinetic energy, i.e. temperature.

The isotope ^4He in the mixture has a nuclear spin $I=0$ and therefore in its liquid state it obeys Bose statistics and undergoes a Bose condensation into the superfluid state at low-enough temperature. This means that the liquid is in a quantum-mechanical ground state, containing essentially no excitations (phonons). Its viscosity, entropy, and specific heat go to zero. In a helium mixture at sufficiently low T, the component ^4He acts as a kind of inert superfluid

background which contributes to the volume of the liquid and to the effective mass of the dissolved ${}^3\text{He}$, but has negligible heat capacitance.

${}^3\text{He}$, on the other hand has nuclear spin $I=\frac{1}{2}$ and is a Fermion, i.e. it obeys Fermi statistics and the Pauli exclusion principle. Its Fermi temperature is very low ($\approx 1\text{K}$), which means that it behaves like a classic gas above 1K , but as a Fermi gas significantly below this temperature. The effects of diluting ${}^3\text{He}$ in ${}^4\text{He}$ can be taken into account as a changed Fermi temperature and changed effective mass.

The ${}^3\text{He}$ atom needs more space than ${}^4\text{He}$ due to its larger zero-point motion (smaller mass). Hence, when a single ${}^3\text{He}$ is put into ${}^4\text{He}$, it is closer to neighboring atoms than it would be in pure ${}^3\text{He}$, and it has more potential (van der Waals) energy. As a consequence, energy is gained by moving ${}^3\text{He}$ to ${}^4\text{He}$. However, due to Pauli repulsion, this effect is over compensated for a specific concentration. This explains the finite solubility of ${}^3\text{He}$ in ${}^4\text{He}$. The stronger binding of ${}^3\text{He}$ in ${}^4\text{He}$ leads to lower kinetic energy, i.e., a reduction in temperature. Note that this considerations would also hold without the finite solubility at 0K . However, for $x \rightarrow 1$ at $T \rightarrow 0$, the process would become very inefficient, which is not the case in the real system.

The enthalpy of mixing is used as the cooling step in a ^3He - ^4He dilution refrigerator. The schematic set up is shown in the slide. Let us follow the flow of ^3He through the device: ^3He gas coming from the exit of a pump at room temperature is first precooled by a liquid ^4He bath at 4.2 K. It will then be condensed to liquid ^3He in a second ^4He bath at 7.5 K, which can be reached by pumping on liquid ^4He . Special care has to be taken in the design of the pre-cooling and condensing unit to allow for efficient heat transfer. The liquid ^3He will flow through a heat exchanger which is in thermal contact with (or even inside) the still at a temperature of about 0.7 K. After this, the liquid ^3He will flow through a series of heat exchangers to precool it as much as possible before it enters the upper, concentrated phase in the mixing chamber. This additional amount of ^3He in the mixture has to be distributed according to the phase diagram shown above. In consequence, the largest part stays in the concentrated phase, but a significant fraction crosses the phase boundary and extracts heat from the surroundings due to the enthalpy of mixing. Because of the finite solubility of ^3He in ^4He even at 0 K, this is an efficient process down to the lowest temperatures.

The dilute phase in the mixing chamber is connected to the almost pure ${}^4\text{He}$ in the still. The different concentrations lead to an osmotic pressure: ${}^3\text{He}$ wants to travel up in order to reach an equilibrium in the concentrations. One can calculate that the osmotic pressure is high enough to lift the ${}^3\text{He}$ by 1 m. After passing the heat exchangers in opposite direction, the ${}^3\text{He}$ enters the strongly diluted phase in the still. The vapor above the diluted phase, however, is almost pure ${}^3\text{He}$ due to its significantly higher vapor pressure compared with ${}^4\text{He}$. This vapor is pumped away by our pumping system, and behind the pump the cycle can start again. A schematic drawing of a real setup is shown in the slide.
